Abstract. Advanced gravitational wave interferometers, currently under realization, will soon permit the detection of gravitational waves from astronomical sources. To open the era of precision gravitational-wave astronomy, a further substantial improvement in sensitivity is required. The future space-based Laser Interferometer Space Antenna (LISA) and the third-generation ground-based observatory Einstein Telescope (ET) promise to achieve the required sensitivity improvements in frequency ranges. The vastly improved sensitivity of the third generation of gravitational-wave observatories could permit detailed measurements of the sources’ physical parameters and could complement, in a multi-messenger approach, the observation of signals emitted by cosmological sources obtained through other kinds of telescopes. This paper describes the progresses of the ET project which is currently in its design study phase.

1. Introduction

Interferometric gravitational wave (GW) detectors have demonstrated the validity of their working principle by coming close to, or even exceeding, the design sensitivity of the initial instruments: LIGO [1], Virgo [2], GEO600 [3] and TAMA [4]. In the same infrastructures, currently hosting the initial GW detectors (and their limited upgrades, called “enhanced” interferometers: eLIGO and Virgo+) a second generation of interferometers (so-called “advanced detectors”: “Advanced LIGO” [5], “Advanced Virgo” [6] and GEO-HF [3]) will be implemented over the next few years. The Laser Interferometer Space Antenna (LISA), a joint ESA-NASA mission expected to fly around 2020, is a space-borne detector to observe in the frequency range of 0.1 mHz to 0.1 Hz — a frequency range that is not accessible from ground. These detectors, based on technologies currently available, and partly already tested in reduced-scale prototypes, but still to be implemented in full scale, will show a sensitivity improved roughly by a factor of ten with respect to the initial interferometers. Hence, a detection rate about a factor of 1000 larger than with the initial interferometers is expected, strongly enhancing the probability of detecting the signals generated by astro-physical sources. In particular, considering the predicted detection rate of the GW signal generated by a binary system of coalescing neutron stars [7], the sensitivity of the advanced interferometers is expected to guarantee the detection within months to a year at most.

Apart from extremely rare events, the signal-to-noise ratio (SNR) of detections in the “advanced” detectors is likely to be still too low for precise astronomical studies of the GW sources and for complementing optical and X-ray observations in the study of fundamental systems and processes in the Universe. This consideration led the GW community to investigate the possibility of building a new (third) generation of detectors, permitting both to observe, with huge SNR, GW sources at distances similar to those detectable in the advanced detectors and to reveal GW signals at distances comparable with the sight distance of the electromagnetic telescopes. As LISA will do for the super-massive black holes ($M \approx 10^6 M_{\text{Sun}}$), ET, thanks to this capability to inspect the GW signal in great detail, could herald a new era of routine GW astronomy for lighter astrophysical bodies.

To realise a third generation GW observatory, with a significantly enhanced sensitivity (considering a target of a factor of ten improvement over advanced detectors in a wide frequency range), several limitations of the technologies adopted in the advanced interferometers must be overcome and new solutions must be developed to reduce the fundamental and technical noises that will limit the next generation detectors. But, mainly, new research facilities hosting the third generation GW observatory apparatuses must be realised, to circumvent the limitations imposed by the current facilities. Hereafter, we will describe some of the possible scientific goals and some of the challenges of a third generation GW observatory, as evaluated within the framework of the Einstein Telescope (ET) design study [8].

2. ET Science reach

In Fig. 1 we plot a possible sensitivity curve of a third generation gravitational wave detector [9]. This is by no means the final design goal but it sets the stage for studying what science questions can be addressed with a third generation detector. A detector with a sensitivity a factor ten better than an advanced detector will open a new avenue

Figure 1. A possible sensitivity (solid curve) of an underground, long suspension, cryogenic, signal and power recycled single third generation gravitational wave observatory (see Table 1 in [9]) compared with a typical sensitivity curve of an advanced detector (dashed curve). It is worth underlining that the evaluation of the possible noise level of a third generation GW observatory is an ongoing activity, still far from being concluded within the ET design study. For this reasons the curves are updated regularly and labeled with progressive letters to be distinguished. In the solid curve (so-called ET-B), corresponding to a single wide-band detector, the suspension thermal noise contribution is not yet included.

for understanding the physical phenomena of extreme objects in the Universe. The study team has started putting together a Vision Document [10] detailing the scope of such a detector. Here we list a few examples of the science questions we can expect to pose with ET.

- (i) Observation of compact binary coalescences would allow accurate measurement of the masses of neutron stars and masses and spins of black holes [11, 12]. For instance, for binaries at a given distance, ET will measure masses and spins an order-of-magnitude better than advanced detectors. More importantly, it should be possible to determine the component masses of binaries to better than 5% (except when the component objects are of comparable masses) over a wide range of masses from a few solar masses to 100's of solar masses. From a population of such observations, it will be possible to infer the maximum mass of a neutron star (a long-standing open problem in theoretical physics) and constrain its equation-of-state [10]. The way this can be done is as follows: It is widely believed that short, hard gamma-ray bursts (shGRBs) are triggered by the coalescence of a compact binary in which one of the stars is a neutron star and the other a neutron star or a black hole. If this is the case, then one can reliably assume that the lighter

of the components of a binary coalescence observed in coincidence is definitely a neutron star. A large enough sample should then give the mass function of neutron stars and tell us where the cutoff in the mass distribution is.

- (ii) Advanced detectors should make first coincident observations of binary mergers and shGRBs. One might not accumulate a sufficiently large population of such events with advanced detectors to fully understand the population of GRBs and their precursors. Advanced detectors could shed light on GRB progenitors (an outstanding problem in astronomy) and ET would allow classification of different types of GRBs, their demography, relationship to masses and spins of component stars, etc.
- (iii) Simultaneous detection of neutrinos, electromagnetic and gravitational radiation from supernovae could help understand the mechanism behind type II supernovae and the astrophysics/physics of gravitational collapse. Furthermore, such observations also help to deduce or constrain the neutrino and graviton masses [13]. ET's range for supernovae is about 5 Mpc, within which one expect a supernova once every 2 to 5 years [14].
- (iv) Comparing observations of massive binary star systems with numerical relativity predictions should allow testing general relativity and constrain alternative theories of gravity (such as the Brans-Dicke theory) [15].
- (v) Inspiralling binary neutron stars (BNS) are ideal standard candles (or standard "sirens"). A population of BNS merger events observed in coincidence with short-hard GRBs can be used to measure cosmological parameters, GW observations helping to accurately estimate the luminosity distance and GRB hosts giving the source redshift [16, 17, 18].
- (vi) ET will be sensitive to intermediate mass black hole binaries of total mass up to about a few thousand solar masses depending on the lower frequency cutoff [19, 20, 21]. The formation, abundance and coalescence rates of such systems is highly uncertain although it is plausible that intermediate mass black holes could be seeds of massive black holes that are now found at galactic nuclei, but they could also form in dense star clusters or by other means. If such systems exist, ET will provide an all sky survey of such objects up to red-shifts of 2 or more.
- (vii) Intermediate black holes irrespective of when and where they form, could grow by accreting other compact objects such as stellar mass black holes and neutron stars. Here again the rates are unknown, but ET will be sensitive to the merger of stellar mass objects onto intermediate black holes at red-shifts of $z = 1$. Such events will be an invaluable tool to study the structure of spacetime geometry near massive black holes [19, 20], even though LISA's observation of stellar mass black holes inspiralling into supermassive black holes would be better at probing the space-time geometry.
- (viii) ET will be able to detect a stochastic background of gravitational waves at the level of $\Omega_{\text{GW}} \sim 10^{-12}$, where Ω_{GW} is the energy density in stochastic background in units of the closure density of the Universe. This compares well with LISA's sensitivity of $\Omega_{\text{GW}} \sim 10^{-11}$ in the frequency range of 2–20 mHz. Although ET's sensitivity is a few orders of magnitude poorer than that required to detect backgrounds predicted by inflationary Universe models, there is the possibility that phase transitions in the early Universe and other processes could give rise to a detectable background [10].

Figure 2. Duration of inspiral signals from binaries of total mass (as given by the x -axis) and mass m_2 of one of the component stars (as in the legend): Signals from binary neutron stars will last for about nine days in the detector band. Many signals will last for more than a day but we will also have very short duration signals from intermediate mass black hole binaries. Curves are shown for mass of one of the components varying from $1M_\odot$ to $1024M_\odot$, increasing by a factor of 2 at each step.

- (ix) At the higher end of its frequency range, ET could observe normal modes in neutron stars excited in a host of astronomical events such as pulsar glitches, magnetar flares, soft-gamma repeaters, etc. GW, optical, X-ray, radio and gamma-ray windows would be invaluable tools for asteroseismology and the best way to probe neutron star interiors and to understand the equation-of-state of matter at extreme conditions of density, pressure, temperature and magnetic fields [10].

3. Challenges for data analysis and the need for new search algorithms

A detector with a sensitivity window and span as ET will pose new data analysis challenges. As in the case of LISA, there will be many classes of sources all visible at the same time, requiring a paradigm shift in the way data are currently being analyzed. Some types of sources that can be assumed to be transients in current detectors will be in ET's band for many hours or even days. For such signals detector motion can no longer be neglected, requiring greater computational costs and the development of new search algorithms. A careful and comprehensive study of the data analysis challenges is currently underway. Here we discuss some of the basic problems a search algorithm should address in the ET era. Most of the following issues are relevant whatever the data analysis method followed, but more so in the case of a matched filtering search, e.g. for binary inspiral signals with a bank of templates.

As far as we can guess, compact binary mergers will dominate the ET observation band. Extrapolating the nominal rate of about one neutron star binary merger event

per year within a distance of 100 Mpc [7] to the distance reach of ET of about 20 Gpc, one expects to detect an event about every 6 seconds. This extrapolation is, of course, not quite correct as it assumes sources to be uniformly distributed in space. In reality, we know that the star formation rate peaks at $z \sim 1$ and so the actual merger rate might be smaller by a moderate factor. Even so, merger signals from binary neutron stars and other compact binaries will be observed quite frequently in ET. We will, therefore, focus on the sort of problems this class of sources might pose.

- (i) Figure 2 plots the duration of binary inspiral signals for systems with various masses, all starting at a frequency of 1 Hz. Remarkably, inspiral signals could stay in the sensitive frequency band for as long as 10 days, for the lightest systems, to as briefly as only a few 100 milliseconds, for the heaviest ones.
- (ii) The preponderance of signals in ET, as opposed to their rare occurrence in the “advanced detectors”, and their long duration means that signals will inevitably overlap with one another and that might cause confusion noise. It is necessary to evaluate the efficiency of the current algorithms in extracting overlapping signals buried in, say, Gaussian noise.
- (iii) The occurrence of many overlapping signals could cause significant degradation of the parameter accuracies and thereby compromise ET’s science potential. Moreover, the presence of many signals invalidates the assumption of stationarity of the data. How reliably can we extract signals and what are the parameter accuracies?
- (iv) At 1 Hz the Doppler modulation due to Earth’s rotation and revolution can be neglected for signals that last for considerably less than one day. For longer signals Doppler modulations in signal amplitude and frequency become important.
- (v) The fact that a source’s location on the sky is changing has to be taken into account in any analysis. Note, however, that at a frequency of 1 Hz the resolution of the detectors, even considering the baseline from the Earth’s motion around the sun over 10 days, is only about 1 str and so this is not likely to be a big problem.
- (vi) The biggest challenge might be matched filtering the data over the entire parameter space of binary systems to which the detector could be potentially sensitive. The number of templates grows roughly as $f_s^{-11/3}$ where f_s is the frequency below which the detector accumulates negligible amount of signal-to-noise. The value of f_s might be a factor 20–40 smaller in going from initial to 3rd generation detectors, thereby leading to a massive increase in the number of search templates and a corresponding increase in the trigger rate. Since the event rate is quite high (an event every 10 or 15 seconds) it might be possible to use sub-optimal techniques to dig out most of the events, and these need to be explored.
- (vii) Neutron stars and stellar mass black holes falling into intermediate mass black holes could last for several days in the band of sensitivity and will have close to millions of cycles. The complex orbits of such systems would pose a serious challenge to the analysis.
- (viii) Amidst millions of binary inspiral signals we could have occasional burst signals from supernovae, neutron star quakes and the associated normal modes, continuous waves from spinning neutron stars, stochastic background of primordial or astrophysical origin, etc. How easy would it be to disentangle these interesting signals and characterize their properties?

The ET study team is working on a set of mock data challenges to test some of the questions posed above. These challenges are similar to the ones carried out in the context of LISA [22] and are open for anyone to participate. Our goal is to produce data sets of increasing complexity in order to provide an opportunity for us to address the data analysis and computational challenges posed by a third generation detector.

4. Technologies in ET

To provide the Einstein Telescope with a sensitivity of a factor of 10 better than that of the “advanced detectors”, the relevant fundamental noise sources should be suppressed (neglecting the role of the so-called “technical” noises): the seismic and gravity gradient noise at very low frequency (1 Hz – 10 Hz), the suspension thermal noise and quantum noise, related to the radiation pressure exerted on the suspended mirror by the photons in the main Fabry–Perot cavities (10 Hz – 40 Hz), the thermal noise of the suspended mirrors (mainly the coating contribution, 40 Hz – 200 Hz) and, finally, at higher frequencies, shot noise component of the quantum noise.

4.1. Seismic and gravity gradient noise reduction

The seismic noise affects the sensitivity at low frequency of the current GW interferometric detectors. In the Virgo detector, the so-called Super-Attenuator (SA) [23], has shown its capability to filter the seismic noise below the expected thermal noise. The performances of the SA have been confirmed to be compliant with the attenuation requirements in Advanced Virgo [24] and, considering as reference a seismic noise linear spectral density of $5 \times 10^{-9}/f^2 \text{ m} \cdot \text{Hz}^{-1/2}$, value measured in the Kamioka (Japan) mine, selected for the construction of the LCGT interferometer [25], it is expected to be easily re-scalable to be compliant with the more restrictive ET noise requirements at low frequency [24].

The gravity gradient noise is due to the direct coupling of the suspended test-mass displacement with the mass vibration in the soil layers, perturbed by seismic waves, via the mutual attraction force expressed by Newton’s universal law of gravitation [26, 27, 28]. Obviously the importance of this disturbance depends on the seismic noise level and on the contribution of the other low-frequency noise sources to the noise budget. In the third generation of GW detectors, the more stringent requirements in terms of sensitivity at low frequency enhance the importance of this noise source and enforce the need to realise the Einstein Telescope in an underground and quiet site.

4.2. Thermal noise reduction

Under the “thermal noise” label are grouped all those processes that modulate the optical path of the light in the interferometer coupling it to the Brownian fluctuation or to the stochastic fluctuation of the temperature field in the optical components. Usually, one distinguishes between the suspension thermal noise, affecting the position of the test masses through the fluctuations of the suspension wires or fibres, and the mirror thermal noise, which is the sum of all the overlapping fluctuation and dissipation processes occurring in the test masses and in its high-reflectivity coatings. The strategies to reduce the thermal noise impact in the second generation GW detectors are essentially an evolution of what has been applied in the initial

detectors and are based on the reduction of the dissipation in the suspension system, in order to concentrate all the fluctuation energy into the normal modes of the system, resulting in a low noise level off-resonance.

In addition to these strategies, in ET we propose to act directly on the total fluctuation energy, by reducing the operative temperature of the suspended optics. Hence, cryogenics is one of the most appealing technologies to reduce the thermal noise of the optics suspension in the third generation of GW observatories. The design of the cryogenic suspension and of its cooling system is progressing in the ET design study and possible material candidates for the test masses and suspension fibres have been identified in sapphire (as already done [29, 30] for LCGT) and silicon [31, 32, 8].

4.3. Quantum Noise reduction

Quantum noise in interferometric gravitational wave detectors can be understood as the coupling of vacuum fluctuations with the optical readout fields inside the interferometer. This coupling causes an uncertainty in the phase and amplitude of the probe beam, which affects the interferometer output signal in two ways: the phase uncertainty directly spoils the phase measurement of the Michelson interferometer; this effect is called *shot noise*. The amplitude uncertainty, or in other words, the changing amplitude of the light, will cause the light pressure on the test masses to change, which correspondingly causes motions of the test masses; this effect is called *radiation pressure noise*. Quantum noise is the sum of shot noise and radiation pressure noise and in the classical Michelson interferometers poses a fundamental limit to the sensitivity of the detector, the so called Standard Quantum Limit (SQL).

Techniques to improve the sensitivity beyond the SQL are called Quantum Noise Reduction (QNR) or somewhat misleadingly Quantum Non-Demolition (QND) schemes. A more detailed introduction to this topic is given in [8], see also [33] for a review of QND schemes discussed in the context of the Einstein Telescope. Currently we aim at using a Michelson interferometer with Signal Recycling and a squeezed light field injected into the interferometer output for reducing the quantum noise in the Einstein Telescope. This method would benefit greatly from a “xylophone” approach (see section 4.4). Alternatively a Sagnac topology is studied as a possible alternative; the Sagnac interferometer is insensitive to radiation pressure noise; so far, however, much less experimental expertise has been gained with this topology.

4.4. Multiple interferometer detector

As described in the previous subsections, to realise a third generation GW detector, the technologies currently operative in the initial and planned for the advanced detectors must be further advanced and new solutions must be adopted. The cross-compatibility between the different solutions becomes a crucial issue; for example, the requirements imposed by the reduction of the quantum noise conflicts with those imposed by the thermal noise suppression. This technological difficulty in realizing a single wide-band third generation detector can be avoided. The base line currently favoured in the ET design study [34] is a combination of two interferometers, specialised on different frequency bands: the so-called xylophone philosophy [35]. Here the output of a low-frequency-specialised detector is combined with the output of a high-frequency machine. The former one could be a cryogenic interferometer at an underground site, with long suspensions, but moderate optical power, whereas

Figure 3. Sensitivity of a third generation GW observatory implemented by two frequency-specialised (LF & HF) detectors (xylophone topology [34], curve so-called “ET-C”), with respect to a single wide frequency range interferometer ET implementation [9].

the high frequency interferometer could essentially be a long arm advanced detector, implementing squeezed light states, a very high power laser and large test masses. A possible realisation of such as xylophone strategy, evaluated in [34] (“ET-C”) for the ET design study, is plotted in Fig. 3 and compared with the single-interferometer implementation (“ET-B”) of the ET observatory, described in [9].

5. Site and infrastructure

In Subsection 4.1 it has been assumed that the required seismic noise spectral density, compliant with the ET sensitivities shown in Fig. 3, corresponds to the noise measured in an underground site. In effect, one of the major activities to be accomplished in the ET design study phase is the identification of the noise requirements of the site hosting the observatory and the compilation of a candidate list in Europe. The first results of this study indicate that the site hosting the ET observatory should be located a few hundred meters underground, in order to reduce the dominant disturbance of the surface seismic waves, in a region with reduced anthropogenic activity, far from main natural noise sources such as the ocean. To reduce the gravity gradient noise a “soft” soil is recommendable, but it causes major construction difficulties and additional costs.

Another important characteristic of the site is the length of the tunnels hosting the main cavities arms. To gain a factor of ten with respect to the advanced detectors, the length of the ET arms should be about 10 km; as this length agrees well with the average lifetime of the tunnel boring machines, which need to be bought, it also optimizes the costs in this respect. In effect, the cost of the site excavation and of the

hosting infrastructure, under evaluation in the ET project, will surely dominate the overall budget of the project. For this reason it will be mandatory to maximise the usage of the site, for example, installing multiple detectors in the tunnels.

5.1. Detector Geometry

All the currently active GW interferometric detectors are L-shaped, with orthogonal arms, since this geometry maximises the sensitivity of a single detector with respect to the arm length. But other geometries are possible, like triangular-shaped detectors already proposed in the past[36], and could become preferable if the selection criteria are more complex than the simple sensitivity maximisation. As analysed in detail in [37], a triangular-shaped observatory, composed of three co-located interferometric detectors, could present many advantages in terms of redundancy, signal reconstruction and cost/benefit minimisation, and this geometry is becoming the baseline option of the ET project.

6. ET Project evolution

The Einstein Telescope design study is supported for three years (2008–2011) within the European Community Seventh Framework Programme (FP7), having the aim of delivering the conceptual design of such a research infrastructure, investigating the technological feasibility, the science targets, the site requirements and prepare a costing draft for the infrastructure.

After this phase, a preparatory activity is expected to be necessary to define the technological details, and the legal and organisational issues. The start of construction (2018–2019) is expected to occur after the first detection of GWs, which is reckoned to happen within at most one year after the advanced detectors will have reached their nominal sensitivity. The construction and commissioning timeline of ET is under study, but about 7–8 years are expected to be necessary before we have the first data available.
